

Lecture 6: The Carbon-14 Clock: Calibration, Contamination, and the Bomb Pulse

CBE 30235: Introduction to Nuclear Engineering — D. T. Leighton

January 27, 2026

1 The Libby Ideal: The Steady-State Clock

In 1949, Willard Libby and his team at the University of Chicago published "Age Determination by Radiocarbon Content: World-Wide Assay of Natural Radiocarbon" (*Science*, 1949). This work laid the foundation for the 1960 Nobel Prize in Chemistry.

1.1 The 1960 Nobel Citation

The Royal Swedish Academy of Sciences awarded the prize to Libby "*for his method to use carbon-14 for age determination in archaeology, geology, geophysics, and other branches of science.*"

The significance of Libby's work was his realization that the Earth's atmosphere acts as a giant, steady-state nuclear reactor. If the production rate (P) has been constant for many half-lives, the total global inventory (I) must be in secular equilibrium.

1.2 Derivation: From 10^{-12} to 15.3 dpm/g

Students often find it hard to visualize how such a trace isotope can be measured. Let's derive the activity from first principles using the "Libby Standard" parameters.

1. **The Ratio:** In a living organism, the isotopic ratio is approximately:

$$\frac{^{14}\text{C}}{^{12}\text{C}} \approx 1.2 \times 10^{-12}$$

2. **Atoms of Carbon per Gram:** One gram of natural carbon (mostly ^{12}C , $MW \approx 12.011$ g/mol) contains N_C atoms:

$$N_C = \frac{1 \text{ g}}{12.011 \text{ g/mol}} \times 6.022 \times 10^{23} \text{ atoms/mol} \approx 5.01 \times 10^{22} \text{ atoms}$$

3. **Atoms of ^{14}C per Gram (N_{14}):**

$$N_{14} = (5.01 \times 10^{22}) \times (1.2 \times 10^{-12}) \approx 6.01 \times 10^{10} \text{ atoms of } ^{14}\text{C}$$

4. **The Decay Constant (λ):** Using the Libby half-life ($T_{1/2} = 5568$ years):

$$\lambda = \frac{\ln(2)}{5568 \text{ years} \times 525,600 \text{ min/year}} \approx 2.37 \times 10^{-10} \text{ min}^{-1}$$

5. The Specific Activity (A):

$$A = \lambda N_{14} = (2.37 \times 10^{-10} \text{ min}^{-1}) \times (6.01 \times 10^{10} \text{ atoms}) \approx \mathbf{14.3 \text{ dpm/g}}$$

Note to Students: While our quick derivation gives ~ 14.3 dpm/g, Libby's empirical measurements of the 1940s biosphere established the "Modern Standard" as **15.3 dpm/g**. This discrepancy highlights the difference between a theoretical estimate and the calibrated standard used in the lab.

1.3 The "Curve of Knowns": Validation of the Clock

Libby knew that for the scientific community to accept "dating by counting," he needed to prove it against established history. He developed the **Curve of Knowns**, plotting the measured radiocarbon age against the known historical age of various artifacts.

- **Egyptian Samples:** Provided by the Metropolitan Museum of Art, these included:
 - **King Zoser's Tomb:** Acacia wood from the 3rd Dynasty (~ 2700 BC).
 - **Sesostris III:** A deck board from a funerary ship (~ 1800 BC).
- **Dendrochronology:** A piece of **Giant Sequoia** heartwood where the rings clearly indicated an age of 2928 ± 52 years.
- **The Result:** When Libby plotted these points, they fell remarkably close to the theoretical decay line. This "Curve of Knowns" was the proof that the atmospheric reservoir was well-mixed and the decay rate was constant over millennia.

2 Natural Variation and Calibration

While Libby's "Standard Model" assumed a constant production rate P , high-precision measurements in the 1950s and 60s revealed that "Radiocarbon Time" and "Calendar Time" do not always march in lockstep.

2.1 The Drivers of Production Flux

As established in Lecture 5, the production of ^{14}C is a function of the secondary neutron flux, which depends on the primary GCR flux hitting the atmosphere. This is modulated by two global shields:

1. **Solar Modulation (Short-term):** The 11-year solar cycle and longer-term "Grand Minima" (like the Maunder Minimum, 1645–1715). Increased solar wind activity effectively "thickens" the heliospheric shield, deflecting GCRs.

2. **Geomagnetic Modulation (Long-term):** The Earth's magnetic field acts as a "band-pass filter." The **Cutoff Rigidity** is the minimum momentum a particle needs to reach a certain latitude. If the Earth's dipole moment weakens (as it has been doing for the last 2,000 years), more cosmic rays reach the atmosphere, increasing P .

2.2 The Reservoir Effect: Why the Clock is "Buffered"

If P varies by 20% over a solar cycle, why doesn't the atmospheric concentration also jump by 20%?

- **The Atmosphere as a Capacitor:** In an engineering circuit analogy, the atmosphere is a small capacitor connected to a massive one (the Deep Ocean).
- **Residence Time:** A Carbon atom stays in the atmosphere for only $\sim 5\text{--}10$ years before being absorbed by the ocean or biosphere. However, the total carbon in the ocean is ~ 50 times greater than the atmosphere.
- **Damping:** This vast exchange reservoir "damps" out short-term spikes. Consequently, we only see the *integrated* effects of solar variation in the ^{14}C record.

2.3 Dendrochronology: The Truth Standard

To correct for these variations, we use **Dendrochronology** (tree-ring dating).

- **Bristlecone Pines:** These trees in the White Mountains of California can live for 5,000 years. By cross-dating dead wood with living trees, researchers have built a continuous "Master Chronology" going back over 12,000 years.
- **The IntCal Collaboration:** Every few years, the international community updates the **IntCal** curve (the current version is IntCal20). It combines data from tree rings, plant macrofossils, and stalagmites (speleothems).

2.4 The "De Vries" Wiggles

The calibration curve is not a smooth line; it has "wiggles" (named after Hessel de Vries).

- **The Plateaus:** Sometimes the curve goes flat. This means that for a period of 200 years, the atmospheric ^{14}C dropped at the exact same rate it was decaying.
- **Engineering Impact:** These plateaus create "ambiguous dates." A sample might map to three different possible calendar years. This is why archaeologists often report dates as a *probability distribution* rather than a single number.

3 Measurement Challenges: The Background Problem

Dating requires measuring a trace isotope ($^{14}\text{C}/^{12}\text{C} \approx 10^{-12}$). This pushes the limits of nuclear detection, as the signal we are looking for is often smaller than the natural "noise" of the universe.

3.1 The "Old" Way: Decay Counting

Early methods used Liquid Scintillation Counters (LSC) or gas proportional counters. Here, we are waiting for a random nuclear event to occur.

- **The Shielding Constraint:** A 1-gram "modern" sample produces only ~ 15 decays per minute. A sample that is 40,000 years old (7 half-lives) produces only **0.1 decays per minute**.
- **Sources of Background:**
 1. **Terrestrial Gamma Rays:** Natural ^{40}K , U, and Th in the laboratory walls.
 2. **Cosmic Ray Muons:** Highly penetrating particles that can trigger the detector.
- **Engineering Solutions:** Labs are often built underground or utilize massive lead shields (often "old lead" from sunken Roman galleys to ensure the lead itself isn't radioactive). **Active Shielding** (anti-coincidence) uses a second detector "wrap" around the primary; if both fire at once, it's a cosmic ray, not a ^{14}C decay, and the count is discarded.

3.2 Statistics and the Limits of Detection

Nuclear decay is a stochastic process. To achieve high precision in dating, we must account for the inherent randomness of the signal and the background.

- **Poisson Statistics:** The number of counts N recorded in a given time interval follows a Poisson distribution. A fundamental property of this distribution is that the standard deviation (σ) is equal to the square root of the number of counts:

$$\sigma = \sqrt{N} \quad (1)$$

- **Relative Precision:** The fractional error (coefficient of variation) is given by:

$$\frac{\sigma}{N} = \frac{\sqrt{N}}{N} = \frac{1}{\sqrt{N}} \quad (2)$$

To achieve a precision of 1%, an engineer must collect at least $N = 10,000$ counts.

- **The Net Count Rate:** In a real lab, we measure a total count rate (R_{tot}) and a background count rate (R_{bg}). The net rate from the sample is $R_s = R_{tot} - R_{bg}$. The uncertainty in the net rate propagates as:

$$\sigma_s = \sqrt{\sigma_{tot}^2 + \sigma_{bg}^2} = \sqrt{\frac{R_{tot}}{t_{tot}} + \frac{R_{bg}}{t_{bg}}} \quad (3)$$

Engineering Implications for the Homework: Consider a 40,000-year-old sample with an activity of 0.1 dpm and a detector background of 1.0 dpm. To distinguish the sample from the background with a 5% relative error, the required counting time t can extend into days or weeks. This statistical "wall" is often what determines the maximum dateable age of a sample more than the sensitivity of the instrument itself.

3.3 The "New" Way: Accelerator Mass Spectrometry (AMS)

AMS revolutionized the field in the late 1970s. Instead of waiting for a decay, we extract the atoms from the sample and count them directly based on their mass and charge.

- **The Sensitivity Challenge:** In a standard mass spec, Nitrogen-14 (^{14}N) is an **isobaric interference**—it has almost exactly the same mass as ^{14}C and is 10^{15} times more abundant in the air.
- **The Engineering "Trick":** AMS uses a tandem accelerator to create negative ions. Crucially, Nitrogen does not form a stable negative ion (N^-), whereas Carbon does (C^-). This "physics filter" removes the Nitrogen background almost entirely.
- **Sample Size:** Because we are counting atoms instead of waiting for decays, we only need **1 milligram** of carbon (the size of a pinhead) rather than grams of wood or bone.

3.4 Statistical Analysis of the Shroud of Turin (1988)

For very precious objects there is no substitute for using AMS for radiocarbon dating. The classic example was the measurement of the age of the Shroud of Turin. Tiny samples cut from a corner were provided to three laboratories. The pooled mean of the three laboratories yielded a radiocarbon age (t) of:

$$t = 691 \pm 31 \text{ BP}$$

Confidence Intervals

Using the **calibration curve** (to account for fluctuations in atmospheric ^{14}C), the radiocarbon age was converted to calendar years:

- 1σ (**68% confidence**): 1273–1288 AD
- 2σ (**95% confidence**): 1262–1384 AD

This was approximately when the Shroud first appeared in the Middle Ages.

3.5 The Ultimate Limit: Why Not 100,000 Years?

Whether using LSC or AMS, we eventually hit a "wall" at approximately **50,000 years**.

- At 10 half-lives (57,300 years), the remaining ^{14}C is 1/1024 of the original. At 50,000 years, the signal becomes indistinguishable from the "instrumental blank."
- **Instrumental Blank:** Even if you put "dead" graphite (millions of years old) into an AMS, the machine might still report a few counts due to tiny amounts of modern CO_2 adsorbed on the machine walls or "memory effects" from the previous sample.

4 Anthropogenic Perturbation 1: The Suess Effect

By the mid-1950s, Hans Suess, a nuclear chemist at the U.S. Geological Survey, recognized that the steady-state assumption of Libby's model was being undermined by human activity. He observed that the specific activity of wood grown in the early 20th century was significantly lower than wood grown in the 19th century.

4.1 The "Radiocarbon Dead" Dilution

The mechanism is straightforward but profound in its impact on global nuclear measurements:

- **Fossil Fuel Origins:** Coal, oil, and natural gas are formed from organic matter buried millions of years ago. Since the half-life of ^{14}C is $\sim 5,730$ years, any initial ^{14}C has decayed through more than 1,000 half-lives ($2^{-1000} \approx 0$).
- **Massive Injection:** Since the Industrial Revolution (~ 1850), the combustion of these fuels has released a massive amount of $^{12}\text{CO}_2$ (and $^{13}\text{CO}_2$) into the atmosphere without any accompanying ^{14}C .
- **The Result:** This "dead carbon" dilutes the atmospheric $^{14}\text{C}/^{12}\text{C}$ ratio. As the denominator (^{12}C) increases while the production rate of the numerator (^{14}C) remains tied to cosmic rays, the relative activity drops.

4.2 Engineering Impact: The "Age" of Modern Air

The Suess effect introduces a "false age" to any organic material that incorporates atmospheric carbon post-1850.

- **The Magnitude:** By 1950, the dilution resulted in a decrease of approximately **2% to 3%** in the ^{14}C concentration relative to 1850 levels.
- **Apparent Age:** In radiocarbon dating, a 1% decrease in activity corresponds to an apparent age increase of about 80 years. Therefore, the Suess effect makes a tree grown in 1950 appear roughly **160–240 years older** than its true calendar age.
- **The 1950 Boundary:** This is why the standard reference for "Modern" in radiocarbon dating is defined as the year ****1950 AD**** (represented as 0 BP, or "Before Present"). After 1950, the nuclear age begins, and the perturbations become even more extreme.

4.3 The Isotopic Fingerprint (^{13}C vs. ^{14}C)

How do we distinguish the Suess Effect from other variations?

- Fossil fuels also have a distinct stable isotope ratio ($^{13}\text{C}/^{12}\text{C}$). Plants prefer ^{12}C over ^{13}C during photosynthesis (fractionation).
- Because fossil fuels are plant-derived, they are "light" in ^{13}C . By measuring the simultaneous drop in both ^{14}C and ^{13}C , atmospheric scientists can prove that the rising CO_2 levels are specifically from fossil fuel combustion rather than volcanic outgassing or biomass burning.

5 Anthropogenic Perturbation 2: The Bomb Pulse

If the Suess Effect was a slow dilution, the "Bomb Pulse" was a global-scale nuclear injection. Between 1952 and 1963, atmospheric thermonuclear testing fundamentally altered the Earth's isotopic signature.

5.1 Mechanism: Artificial Neutron Flux

Thermonuclear (fusion) bombs release a massive burst of high-energy neutrons.

- These neutrons undergo the same (n, p) reaction with atmospheric ^{14}N that GCRs do, but at a rate millions of times higher.
- **The Peak:** By 1963, the atmospheric ^{14}C concentration in the Northern Hemisphere reached approximately **200% of the pre-industrial level** (often referred to as 200 "Percent Modern Carbon" or pMC).
- **The Partial Test Ban Treaty (1963):** After the cessation of atmospheric testing, the production rate returned to the natural GCR baseline, but the "Pulse" remained in the atmosphere.

5.2 The "Disappearance" of the Pulse

The concentration of ^{14}C in the air has been dropping steadily since 1964.

- **It is not decaying!** With a 5,730-year half-life, negligible decay has occurred.
- **Sequestration:** The pulse is disappearing because it is being absorbed into the **Oceanic Reservoir** and the **Terrestrial Biosphere**. This provides oceanographers with a "tracer" to measure the rate of deep-water formation and global CO_2 uptake.

5.3 Engineering Applications: The Modern Timestamp

Because the ^{14}C concentration changed by several percent every year during the decline of the pulse, we can use it as a high-precision chronometer for anything biological formed after 1955.

1. **Forensic Science:** We can date the formation of "permanent" tissues. For example, the crystalline proteins in the **lens of the human eye** do not turnover. Measuring the ^{14}C in a lens can determine a person's birth year to within ± 1.5 years.
2. **Anti-Poaching:** Forensic scientists date the "base" of an elephant tusk. If the radiocarbon date is post-1989 (the international ivory ban), the ivory is confirmed as illegal contraband rather than a legal "antique."
3. **Fine Wine Authentication:** If a bottle of "1945 Chateau Mouton Rothschild" contains any "Bomb Carbon," it is a confirmed fake. The presence of ^{14}C above 100 pMC proves the grapes were grown after 1955.

5.4 The "Cross-over" and the Future of Dating

We are currently living through a unique period in nuclear history.

- As of the early 2020s, the dilution from the ****Suess Effect**** (adding dead ^{12}C) and the removal of the ****Bomb Pulse**** (sequestering ^{14}C) have caused the atmospheric ratio to return to the 1850 "natural" baseline.
- Moving forward, atmospheric ^{14}C will continue to drop *below* the pre-industrial level due to fossil fuel emissions. This creates a "dating paradox" where a piece of wood grown in 2025 might date as being 500 years old.

6 Conclusion: The Tracer of the Anthropocene

The transition from Willard Libby's "Ideal Clock" to the modern "Dynamic Model" illustrates a fundamental principle in nuclear engineering: **the importance of understanding the source term and the reservoir kinetics.**

6.1 The New Standard Model

We no longer view ^{14}C as a constant. Instead, the "Standard Model" today is a complex interplay of three factors:

1. **Natural Production:** Modulated by the Sun and the Earth's magnetic field (The "Wiggles").
2. **The Industrial Dilution:** The Suess Effect "ages" the atmosphere by injecting radiocarbon-dead CO_2 .
3. **The Nuclear Spike:** The Bomb Pulse provides a localized "delta-function" input that allows us to track the movement of carbon in real-time.

6.2 The Ultimate Global Tracer

For the modern engineer, ^{14}C is much more than a dating tool; it is a **global tracer** for mass transport:

- **Atmospheric Mixing:** By watching the Bomb Pulse move from the Northern Hemisphere to the Southern Hemisphere in the 1960s, scientists were able to calculate the *interhemispheric mixing time* ($\sim 1\text{--}2$ years).
- **Oceanic Sequestration:** Tracking how ^{14}C enters the "Deep Ocean Conveyor" allows us to model how effectively the oceans can mitigate climate change by absorbing excess anthropogenic CO_2 .
- **Biological Turnover:** From the eye lenses of sharks to the turnover of carbon in human heart cells, the Bomb Pulse allows us to measure the metabolic rates of life itself.

6.3 Final Synthesis

Radiocarbon dating remains one of the most elegant applications of nuclear physics. It requires an understanding of **nuclear reactions** (production), **radioactive decay** (the clock), **analytical chemistry** (sample prep and background), and **mass spectrometry** (measurement).

As we move further into the 21st century, the "Bomb Pulse" will continue to fade and the "Suess Effect" will continue to grow. The challenges of tomorrow's nuclear engineers will include disentangling these human signatures to understand the natural world that Willard Libby first began to measure in 1949.

Technical Note: Analyzing the C14 Bomb Pulse

1 Partitioning of Marine Carbon (Surface Waters)

In the upper euphotic zone (0–10 m), carbon exists in a multi-phase equilibrium. For radiocarbon studies, it is essential to distinguish between the dissolved "reservoir" and the particulate "flux."

- **Dissolved Inorganic Carbon (DIC):** > 95% of total carbon. Comprised of HCO_3^- ($\sim 91\%$), CO_3^{2-} ($\sim 8\%$), and dissolved CO_2 ($\sim 1\%$). This pool is in isotopic equilibrium with atmospheric $^{14}CO_2$.
- **Dissolved Organic Carbon (DOC):** $\sim 3\%$ of total carbon. Consists of complex organic molecules (humic acids, etc.). Its ^{14}C signature often shows a "bulk age" of thousands of years due to refractory components.
- **Particulate Organic Carbon (POC):** < 1% of total carbon. This includes the "biota" (plankton, krill, fecal pellets). While mass-insignificant, it is the primary vehicle for the **Biological Pump**, transporting ^{14}C to the deep ocean.

The Measurement Challenge: When sampling seawater for ^{14}C dating, one must decide whether to measure the *bulk* water (DIC) or filter the water to measure the *particulates* (POC). In surface waters, their $\Delta^{14}C$ signatures are generally identical, but in the deep ocean, the "sinking" POC is much "younger" than the surrounding DIC.

2 Inter-Hemispheric Mixing Model

To model the transport of the ^{14}C pulse, we treat the atmosphere as two reservoirs (North and South) separated by a resistive barrier (the ITCZ).

The rate of change in the Southern Hemisphere concentration (C_S) is proportional to the gradient between the hemispheres:

$$\frac{dC_S}{dt} = k(C_N - C_S) - \lambda C_S$$

Where:

- C_N, C_S = ^{14}C concentration in Northern and Southern Hemispheres.
- k = Inter-hemispheric exchange rate constant (≈ 0.6 to 1.0 yr^{-1}).
- λ = Combined rate of removal (oceanic uptake + radioactive decay).

The Time Constant: The exchange time (τ_{ex}) is the reciprocal of the rate constant:

$$\tau_{ex} = \frac{1}{k} \approx 1 \text{ to } 1.5 \text{ years}$$

Significance: This lag allowed scientists to calibrate global circulation models (GCMs), ensuring we accurately understand how pollutants, CO_2 , and radioactive fallout distribute globally.

3 Kinetic Modeling of the Bomb Pulse Decline

The atmosphere (a) and surface ocean (s) exchange carbon at a rate determined by the exchange coefficient k_{as} . The change in the atmospheric radiocarbon inventory (I_a) can be modeled as:

$$\frac{dI_a}{dt} = -k_{as}I_a + k_{sa}I_s - \lambda_{bio}I_a$$

Where:

- k_{as} = Air-to-sea transfer rate (yr^{-1}).
- I_a, I_s = Carbon inventory in the atmosphere and surface ocean.
- λ_{bio} = Rate of uptake by the terrestrial biosphere.

The Dilution Factor and Reservoir Size: The "apparent" decay constant observed in the bomb pulse ($\lambda_{obs} \approx 0.05 \text{ yr}^{-1}$) implies an e -folding time of roughly 14–16 years. This rate is controlled by the **ratio of the inventories**:

$$\frac{Flux_{net}}{I_{atm}} \propto \text{Exchange Velocity} \times \frac{Area}{Volume_{atm}}$$

Note: If the ocean reservoir were smaller, the "back-pressure" ($k_{sa}I_s$) would increase more rapidly, slowing down the atmospheric decay. Because the deep ocean reservoir is so vast ($\sim 45 \times$ the atmosphere), it prevents the surface from saturating quickly.

4 Ocean Ventilation and the ^{14}C Clock

To determine the velocity of deep-ocean currents, we calculate the *Apparent Radiocarbon Age* of a water mass. We compare the measured ^{14}C activity (A_{sample}) to the activity the water had when it was last at the surface ($A_{surface}$).

The Age Equation:

$$t = -8033 \cdot \ln \left(\frac{A_{sample}}{A_{surface}} \right)$$

Correction for the Reservoir Effect: Surface water is not in perfect equilibrium with the atmosphere. It usually appears "older" by about 400 years due to the upwelling of old, deep water. This is corrected using the $\Delta^{14}\text{C}$ notation:

$$\Delta^{14}\text{C} = \left(\frac{(A_{sample}/A_{standard}) \cdot e^{\lambda(y-1950)} - 1}{1} \right) \times 1000\%$$

Modeling Current Velocity: By measuring the distance (Δd) between two sampling stations along a flow path (e.g., the North Atlantic Deep Water) and the difference in their radiocarbon ages (Δt), we can estimate the average current velocity:

$$v_{current} = \frac{\Delta d}{\Delta t}$$

Note: Typical velocities for the deep conveyor belt are on the order of centimeters per second, leading to transit times across the Atlantic basin of several centuries.

Technical Note: Accelerator Mass Spectrometry (AMS)

1 Introduction: Counting Atoms vs. Counting Decays

Radiocarbon dating was originally performed by measuring the beta decay activity of a sample. The decay follows the law:

$$\frac{dN}{dt} = -\lambda N \quad (4)$$

Because the half-life of ^{14}C is long ($t_{1/2} = 5730$ years), the decay constant λ is very small ($\lambda \approx 1.21 \times 10^{-4} \text{ yr}^{-1}$). Consequently, obtaining statistically significant counts from small samples required weeks of observation.

Accelerator Mass Spectrometry (AMS) revolutionized this field by measuring N (the number of atoms) directly, rather than dN/dt (the decay rate). This increases sensitivity by factors of 10^3 to 10^4 , allowing for the dating of milligram-sized samples in minutes.

2 The Challenge: Isobaric Interference

The primary difficulty in detecting ^{14}C is not just its scarcity (~ 1 part per trillion relative to ^{12}C), but the presence of **Nitrogen-14** (^{14}N).

- ^{14}N is the most abundant gas in the atmosphere and a common contaminant in samples.
- The mass difference between ^{14}C and ^{14}N is too small for standard mass spectrometers to resolve easily.

AMS utilizes specific nuclear physics phenomena to eliminate this background completely.

3 The AMS Mechanism

The AMS process for ^{14}C involves four distinct stages of filtration.

3.1 1. The Ion Source (The Negative Ion Filter)

The sample is graphitized and bombarded with Cesium ions (Cs^+) to produce a beam of negative ions.

- Carbon forms a stable negative ion: $^{14}\text{C}^-$.
- Nitrogen **does not** form a stable negative ion. Nitrogen anions are unstable and dissociate almost instantly.

Result: By selecting for negative ions at the source, the ^{14}N isobaric interference is effectively eliminated ($\sim 100\%$ suppression).

3.1.1 Physics of the Sputter Source: Why Cs^+ yields C^-

It may seem counterintuitive that bombarding a target with positive ions (Cesium, Cs^+) results in the ejection of negative ions (Carbon, C^-). The mechanism relies on surface physics, specifically the interplay between the **Work Function** and **Electron Affinity**.

The process occurs in three distinct steps:

1. **Surface Modification (Lowering Φ):** The Cesium ions do not merely act as projectiles; they also coat the surface of the carbon sample. Cesium is an alkali metal with a very low ionization energy. The deposition of a partial monolayer of Cesium drastically lowers the **Work Function** (Φ) of the sample surface. This makes the surface electrons "looser" and energetically easier to remove.
2. **Sputtering (Momentum Transfer):** The incident high-energy Cs^+ ions (typically 3 – 6 keV) collide with the graphite lattice. Through kinetic momentum transfer, neutral Carbon atoms are knocked out of the lattice and pass through the Cesium-rich surface layer as they exit into the vacuum.
3. **Electron Tunneling (Charge Exchange):** As a neutral Carbon atom departs the surface, it interacts with the surface electron cloud.
 - Carbon has a high **Electron Affinity** ($E_{ea} \approx 1.26$ eV), meaning it is energetically favorable for it to acquire an extra electron.
 - Because the Cesium-coated surface has a low Work Function, the energy barrier for electron transfer is reduced.
 - An electron quantum-mechanically **tunnels** from the surface to the departing Carbon atom, converting it into a C^- ion.

Why this eliminates Nitrogen: This specific mechanism is the primary reason AMS is feasible for radiocarbon dating. While Carbon has a positive electron affinity (+1.26 eV), Nitrogen has a **negative** electron affinity. Even with the lowered work function of the Cesium surface, Nitrogen atoms are energetically forbidden from accepting an electron to form stable N^- ions. Consequently, the beam emerging from the source is effectively free of ^{14}N .

3.2 2. Low-Energy Mass Selection

The negative ion beam is passed through an injector magnet which bends the beam based on mass ($q\mathbf{v} \times \mathbf{B}$). The system selects for Mass 14.

Remaining Contaminants: While ^{14}N is gone, the beam still contains molecular isobars with Mass ≈ 14 , such as $^{13}\text{CH}^-$ and $^{12}\text{CH}_2^-$.

3.3 3. The Tandem Accelerator (Molecular Destruction)

The beam enters a Tandem Van de Graaff accelerator.

1. **Acceleration:** The negative ions are attracted to the positive terminal (typically 2–6 MV) at the center of the accelerator.
2. **Electron Stripping:** At the terminal, the ions pass through a thin carbon foil or gas canal (stripper). This strips multiple electrons from the ions, converting them from negative to highly positive (e.g., C^{3+}).
3. **Coulomb Explosion:** Molecules like ^{13}CH cannot exist in a highly positive state (e.g., C^{3+}H^+). The lack of binding electrons causes the nuclei to repel each other violently, breaking the molecule apart.

Result: All molecular isobars are destroyed. Only atomic carbon ions survive the acceleration process.

3.4 4. High-Energy Analysis and Detection

The now positive C^{3+} ions are accelerated away from the positive terminal, achieving energies in the MeV range.

- **Magnetic Filtering:** A high-energy analyzing magnet filters the beam by momentum ($p = mv$).
- **Electrostatic Filtering:** An electrostatic analyzer (or Wien filter) selects for velocity, removing any fragments from the Coulomb explosions.
- **Ionization Detection:** The final detector is a gas ionization chamber. It measures:
 - Total Energy (E_{total})
 - Rate of Energy Loss (dE/dx)

Since $dE/dx \propto Z^2$, this allows for definitive discrimination between Carbon ($Z = 6$) and any rogue isobars, providing a background-free count of ^{14}C atoms.
